1 Determining the Optimal Portfolio Allocation with Cryptocurrency

Assumptions: 1. The investor defines the standard deviation of the asset's returns from their mean (expected return), as a measure of risk. 2. The portfolio risk, σ_p depends on the variances of assetsin the portfolio and on the covariance between them. 3. The investor allocates the asset's weights in the portfolio to *minimize* the portfolio return risk σ_p for any desired portfolio expected returns.

1.1 Generating Risk-Return Profiles for a given set of financial instruments, and their statistical characteristics

- The goal of this is to implement a Monte Carlo simulation to generate random portfolio weight vectors on a larger scale.
- For *every simulated allocation*, the code records the resulting expected portfolio return and variance.
- Here I define two functions: **port_ret()** and **port_vol**

[ ]:
```
weights = np.random.random(noa)
weights /= np.sum(weights)
```

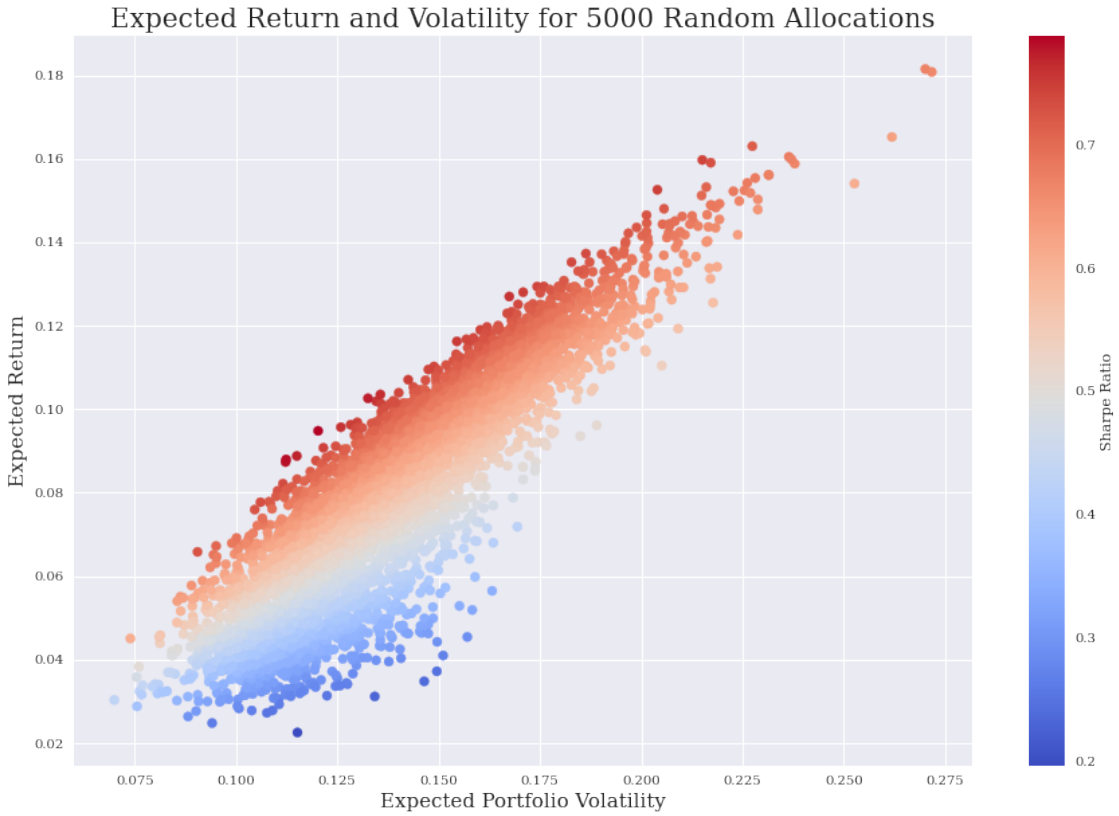
[ ]:
```
0.9999999999999999
```

[ ]:
```
def port_ret(weights):
    return np.sum(log_returns.mean() *weights)*252
def port_vol(weights):
    return np.sqrt(np.dot(weights.T,np.dot(log_returns.cov()*252, weights)))
prets = []
pvols = []
for p in range(5000):
```

```
    weights = np.random.random(noa)
    weights /= np.sum(weights)
    prets.append(port_ret(weights))
    pvols.append(port_vol(weights))
prets = np.array(prets)
pvols = np.array(pvols)
```

[ ]:
```
from scipy.ndimage import label

plt.figure(figsize = (15,10))
plt.scatter(pvols, prets, c = prets/pvols,marker = 'o', cmap = "coolwarm")
plt.xlabel("Expected Portfolio Volatility", fontsize = 15)
plt.ylabel("Expected Return", fontsize = 15)
plt.title("Expected Return and Volatility for 5000 Random Allocations", size =␣
↪20)
plt.colorbar(label = "Sharpe Ratio")
plt.show()
```



-It is clear from the picture above that not all weight distributions perform well when measured in terms of mean an volatility. For every fixed level risk, we can see their are multiple portfolios that

show different returns. - As an investor one is generally interested in the maximum return given a fixed level of risk or the *minimum risk given a fixed return expectation.* - This set of portfolios then makes up the so-called **efficient frontier.**

1.2 Optimal Portfolios

-The **minimization** function is general and allows for equality constraints, inequality constraints, and numerical bounds for the parameters. -The **maximization of the Sharpe ratio.** Formally, the negative value of the Sharpe ratio is minimized to derive at the maximum value and the optimal portfolio composition. The constraint is that all parameters (weights) add up to 1. This can be formulated using the conventions of the **minimize()** function.The parameters values (weights) are also bound to be between 0 and 1. These values are povided to the minimization function as a tuple of tuples.

[ ]:
```
import scipy.optimize as sco

def min_func_sharpe(weights):
    return -port_ret(weights)/port_vol(weights)
cons = ({'type': 'eq', 'fun': lambda x: np.sum(x)-1})
bnds = tuple((0,1) for x in range(noa))
eweights = np.array(noa*[1./noa,])
eweights
min_func_sharpe(eweights)
```

[ ]:
```
-0.6033009115064529
```

-Calling the function returns more than just optimal parameter values. THe results are stored in an object called **opts.** -The main interest lies in getttin gthe optimmal portfolio composition.

[ ]:
```
opts = sco.minimize(min_func_sharpe, eweights, method = "SLSQP", constraints =␣
 ↪cons)
pd.DataFrame(opts['x'], index = ["Short Treasury", "Bitcoin", "Commodity",␣
 ↪"Emerging Markets", "SPY","TIPs", "20 Year Bonds", "Foreign Equity", "Real␣
 ↪Estate", "Russell 2000"], columns = ["Weights"])
```

[ ]:

	Weights
Short Treasury	0.785345
Bitcoin	0.020773
Commodity	-0.007282
Emerging Markets	-0.067393
SPY	0.404471
TIPs	0.258288
20 Year Bonds	-0.086074
Foreign Equity	-0.170488
Real Estate	-0.046447
Russell 2000	-0.091193

[ ]:
```
print("The resulting portfolio return and portfolio volatility from the optimal␣
 ↪weights are", np.round(port_ret(opts['x']),4), "and",np.
 ↪round(port_vol(opts["x"]),4), "respectively.")
```

```
The resulting portfolio return and portfolio volatility from the optimal weights
are 0.0512 and 0.0364 respectively.
```

- Next, the **Minimization of the Variance of the Portfolio.**This is the same as minimizing the volatility.

[ ]:
```
optv = sco.minimize(port_vol, eweights, method = "SLSQP", bounds = bnds,␣
 ↪constraints = cons)
pd.DataFrame(optv['x'], index = ["Short Treasury", "Bitcoin", "Commodity",␣
 ↪"Emerging Markets", "SPY","TIPs", "20 Year Bonds", "Foreign Equity", "Real␣
 ↪Estate", "Russell 2000"], columns = ["Weights"])
```
